We introduce a new family of trial wave-functions based on deep neural networks to solve the many-electron Schrödinger equation. The Pauli exclusion principle is dealt with explicitly to ensure that the trial wave-functions are physical. The optimal trial wave-function is obtained through variational Monte Carlo and the computational cost scales quadratically with the number of electrons. The algorithm does not make use of any prior knowledge such as atomic orbitals. Yet it is able to represent accurately the ground-states of the tested systems, including He, H<sub>2</sub>, Be, B, LiH, and a chain of 10 hydrogen atoms. This opens up new possibilities for solving large-scale many-electron Schrödinger equation.

Keywords:

An accurate quantum mechanical treatment of the interaction between many electrons and ions is the foundation for modeling physical, chemical, and biological systems. Theoretically, these systems are described by the many-electron Schrödinger equation, which consists of the kinetic and Coulomb interaction terms [1]. However, solving the Schrödinger equation accurately for real physical systems has been prohibitively difficult due to the high dimensionality of the Hilbert space involved, the high degree of entanglement produced by the electron-electron and electron-ion interactions, and the notorious Pauli exclusion principle imposed on the wave-function, i.e., the wave-function has to change its sign when two identical electrons exchange places [2].

Developing efficient algorithms for this problem is among the most heroic endeavors in computational science and is still an ongoing quest. An incomplete list of the major methodologies developed so far includes the Hartree-Fock (HF) based methods [3, 4], configuration interaction (CI) based methods [5–8], coupled cluster (CC) based schemes [9–12], Monte Carlo-based approaches [13–20], and the more recently developed density matrix renormalization group (DMRG) theory [21–25] and density matrix embedding theory (DMET) [26–28]. We refer to Refs. [29–31] for a more detailed review of these advances.

Of particular interest to this work is the variational Monte Carlo (VMC) scheme which uses variational principle and Monte Carlo sampling to obtain the best parametrized trial wave-function [13–15, 20]. Naturally the key component is the representation of the trial wave-functions. The most commonly used trial wave-functions typically consist of an anti-symmetric Slater determinant [32] multiplied by a symmetric Jastrow correlation factor [33]. There have been tremendous efforts on im-

proving the nodal surface (a subspace on which the function value equals zero and across which it changes the sign) of the anti-symmetric part of the trial wave-function and the representability of the symmetric part [34–36].

With remarkable successes in many fields such as computer vision and speech recognition, the deep neural network (DNN) has shown great capacity in approximating high-dimensional functions (see e.g. review [37] and the references therein). Furthermore, DNN has been successfully used in solving general high-dimensional partial differential equations [38–41] and certain quantum many-body problems for Bosonic and lattice systems [42–46]. However, there have been few attempts to solve the many-electron Schrödinger equations based on DNN, and this constitutes the main objective of this work.

To achieve this, we develop a general and efficient DNN representation for the many-electron wave-function satisfying the Pauli exclusion principle. The resulted trial wave-function can naturally fit into the framework of VMC to optimize the parameters in our model. As preliminary tests, we show that this DNN-based trial wave-function is able to produce reasonably well ground-state energies for some small systems, such as Be, B, LiH, and a chain of 10 hydrogen atoms (H<sub>10</sub>). We find that, learning from scratch without any prior knowledge and without resorting to a reference of atomic bases, the DNN-based wave-function is able to reproduce the shell structure of Be and B, potential energy curves of H<sub>2</sub> and H<sub>10</sub>, etc. We call the methodology introduced here the *DeepWF* method. This paper only reports our initial results. There is still a huge room for improvement.

We consider a system of  $N$  electrons and  $M$  ions, under the Born-Oppenheimer approximation [47]. This system

FIG. 1: Schematic plot of DeepWF, taking H<sub>10</sub> as an example.  $\mathbf{r}^\uparrow$  and  $\mathbf{r}^\downarrow$  denote the positions of 5 electrons of spin-up and 5 of spin-down, respectively, and  $\mathbf{R}^H$  denotes the positions of 10 hydrogen atoms. (a) the entire wave-function  $\Psi(\mathbf{r}; \mathbf{R}) = S(\mathbf{r}; \mathbf{R})A^\uparrow(\mathbf{r}^\uparrow)A^\downarrow(\mathbf{r}^\downarrow)$ , decomposed into symmetric function  $S(\mathbf{r}; \mathbf{R})$  and two anti-symmetric functions  $A^\uparrow(\mathbf{r}^\uparrow)$ ,  $A^\downarrow(\mathbf{r}^\downarrow)$ , with respect to spin-up and spin-down electrons; (b) anti-symmetric function  $A^\uparrow(\mathbf{r}^\uparrow)$  for spin-up electrons; (c) symmetric function  $\tilde{S}_i(\mathbf{r}^i)$  as the contribution of particle  $i$  in the symmetric function  $\log(S^2(\mathbf{r}; \mathbf{R}))$ . See text for detailed explanations.

is described by the Hamiltonian

$$\hat{H} = -\frac{1}{2} \sum_{i=1}^N \nabla_i^2 + \sum_{i=1}^N \sum_{j=i+1}^N \frac{1}{|\mathbf{r}_i - \mathbf{r}_j|} - \sum_{I=1}^M \sum_{i=1}^N \frac{Z_I}{|\mathbf{r}_i - \mathbf{R}_I|} + \sum_{I=1}^M \sum_{J=I+1}^M \frac{Z_I Z_J}{|\mathbf{R}_I - \mathbf{R}_J|}, \quad (1)$$

where  $\mathbf{r} = (\mathbf{r}_1, \dots, \mathbf{r}_N)$  and  $\mathbf{R} = (\mathbf{R}_1, \dots, \mathbf{R}_M)$  are the coordinates of the electrons and the ions, respectively, and the  $Z_I$ 's are the nuclear charges. Since  $\hat{H}$  is spin-independent, it is valid to assume that the first  $N_\uparrow$  electrons are of spin-up and the remaining  $N_\downarrow = N - N_\uparrow$  electrons are of spin-down [20]. Accordingly, we can write the wave-function in a spin-independent form  $\Psi(\mathbf{r}; \mathbf{R})$ . Let  $N_{\text{tp}}$  be the number of ion types in the system, then there are  $N_{\text{tp}} + 2$  types of particles in total, taking into account the electrons of spin-up and spin-down separately.

In this work we restrict our attention to the ground state of the system. The variational principle states that the wave-function associated with the ground state  $\Psi_{\text{ground}}$  minimizes within the required symmetry the following energy functional

$$E[\Psi] = \frac{\int \Psi^*(\mathbf{r}; \mathbf{R}) \hat{H} \Psi(\mathbf{r}; \mathbf{R}) d\mathbf{r}}{\int \Psi^*(\mathbf{r}; \mathbf{R}) \Psi(\mathbf{r}; \mathbf{R}) d\mathbf{r}}.$$

We now discuss how to represent the wave-function  $\Psi(\mathbf{r}; \mathbf{R})$  with DNN. The trial wave-functions are assumed to be real-valued. The primary goal is to ensure that the represented wave-function satisfies the anti-symmetry property. To this end, we decompose the

wave-function as  $\Psi(\mathbf{r}; \mathbf{R}) = S(\mathbf{r}; \mathbf{R})A^\uparrow(\mathbf{r}^\uparrow)A^\downarrow(\mathbf{r}^\downarrow)$ , where  $\mathbf{r}^\uparrow, \mathbf{r}^\downarrow$  denote the positions of spin-up and spin-down electrons, respectively. We require  $S(\mathbf{r}; \mathbf{R})$  to be symmetric and  $A^\uparrow(\mathbf{r}^\uparrow), A^\downarrow(\mathbf{r}^\downarrow)$  to be both anti-symmetric. As an analogy, one can view  $S(\mathbf{r}; \mathbf{R})$  as a Jastrow factor and  $A^\uparrow(\mathbf{r}^\uparrow), A^\downarrow(\mathbf{r}^\downarrow)$  as Slater determinant-like functions. The main difference is that we aim to obtain a good parametrization of these three functions jointly from an end-to-end learning process instead of specifying the specific form of these functions as in conventional VMC. In practice,  $\log(\Psi^2(\mathbf{r}; \mathbf{R}))$  is more convenient for implementing VMC. From this perspective, the introduced decomposition of wave-function becomes

$$\log(\Psi^2(\mathbf{r}; \mathbf{R})) = \tilde{S}(\mathbf{r}; \mathbf{R}) + \log(|A^\uparrow(\mathbf{r}^\uparrow)|^2) + \log(|A^\downarrow(\mathbf{r}^\downarrow)|^2), \quad (2)$$

where  $\tilde{S}(\mathbf{r}; \mathbf{R}) := \log(S^2(\mathbf{r}; \mathbf{R}))$  is still a general symmetric function. On the other hand, although being symmetric,  $\log(|A^\uparrow(\mathbf{r}^\uparrow)|^2)$  and  $\log(|A^\downarrow(\mathbf{r}^\downarrow)|^2)$  have singularities on the nodal surface. Therefore we need to secure this property by representing  $A^\uparrow(\mathbf{r}^\uparrow)$  and  $A^\downarrow(\mathbf{r}^\downarrow)$  directly. In the following we discuss how to represent  $A^\uparrow(\mathbf{r}^\uparrow), A^\downarrow(\mathbf{r}^\downarrow)$ , and  $\tilde{S}(\mathbf{r}; \mathbf{R})$  with DNN and how to learn the optimal parameters using VMC. See Fig. 1 for a schematic illustration.

The basic building block for the anti-symmetric function  $A^\uparrow(\mathbf{r}^\uparrow)$  is an ansatz

$$a^\uparrow(\mathbf{r}^\uparrow) = \prod_{1 \leq i < j \leq N_\uparrow} a_0^\uparrow(r_i, r_j), \quad (3)$$

where  $a_0^\uparrow$  is a general two-body anti-symmetric func-

tion with  $M_1$ -dimensional output, i.e.,  $\mathbf{a}_0^\uparrow(\mathbf{r}_i, \mathbf{r}_j) = -\mathbf{a}_0^\uparrow(\mathbf{r}_j, \mathbf{r}_i)$ , and the products are component-wise. In (3) we have assumed  $N_\uparrow \geq 2$ . Such representation can be viewed as a generalization of the Laughlin wave-function [48], which describes well the anomalous quantum Hall effect. In practice, we let  $\mathbf{a}_0^\uparrow(\mathbf{r}_i, \mathbf{r}_j) = \text{Net}_{\text{anti}}^\uparrow(\mathbf{r}_i, \mathbf{r}_j, r_{ji}) - \text{Net}_{\text{anti}}^\uparrow(\mathbf{r}_i, \mathbf{r}_j, r_{ji})$ , in which  $\text{Net}_{\text{anti}}^\uparrow(\cdot)$  is a DNN that concatenates all the input variables together as network input. By convention  $r_{ji} = |\mathbf{r}_{ji}| = |\mathbf{r}_j - \mathbf{r}_i|$  denotes the Euclidean distance between particles  $i$  and  $j$ . Next  $\mathbf{a}^\uparrow$  is fed into another DNN  $\text{Net}_{\text{odd}}^\uparrow$ , which satisfies  $\text{Net}_{\text{odd}}^\uparrow(\mathbf{x}) = -\text{Net}_{\text{odd}}^\uparrow(-\mathbf{x})$ , and outputs a scalar. We can further adjust its scale and define  $A^\uparrow(\mathbf{r}^\uparrow)$  through  $\log |A^\uparrow(\mathbf{r}^\uparrow)| = f_{\text{odd}} \log |\text{Net}_{\text{odd}}^\uparrow(\mathbf{a}^\uparrow(\mathbf{r}))|$  where  $f_{\text{odd}}$  is a positive scalar factor. The sign of  $A^\uparrow(\mathbf{r}^\uparrow)$  is taken as the same as  $\text{Net}_{\text{odd}}^\uparrow(\mathbf{a}^\uparrow(\mathbf{r}^\uparrow))$  such that  $A^\uparrow(\mathbf{r}^\uparrow)$  inherits the anti-symmetry. The same argument and construction introduced above are applied to spin-down electrons and yield  $A^\downarrow(\mathbf{r}^\downarrow)$ .

While DNN-based anti-symmetric function has seldom been investigated in the literature, DNN-based symmetric function has gained wide attentions recently in modeling many-body potential energy surface [49–53], free energy surface [54–56], etc. For instance, the Deep Potential-Smooth Edition (DeepPot-SE) model is able to efficiently describe the interatomic potential energy of both finite and extended systems, with the accuracy of *ab initio* quantum mechanics models [52]. A crucial step there is to faithfully map the input atomic coordinates onto a symmetry-preserving feature space. Therefore, it shares the symmetric property of the Jastrow factor, and might become a more general Jastrow factor that is able to better capture the many-body correlations between the electrons and ions.

We extend the DeepPot-SE model to construct  $\tilde{S}(\mathbf{r}; \mathbf{R})$ . For later convenience we regard  $\mathbf{R}$  as  $(\mathbf{r}_{N+1}, \dots, \mathbf{r}_{N+M})$  and let  $\tilde{\mathbf{r}} := (\mathbf{r}_1, \dots, \mathbf{r}_{N+M})$ . For each particle  $i$ , we consider its neighboring environment in terms of the Cartesian coordinates:

$$\mathcal{R}^i = \{\mathbf{s}(\mathbf{r}_{1i})^T, \dots, \mathbf{s}(\mathbf{r}_{ji})^T, \dots\}^T \in \mathbb{R}^{(N+M-1) \times 4}, \quad (4)$$

where  $\mathbf{s}(\mathbf{r}_{ji}) = (\mathbf{r}_{ji}/r_{ji}^2, 1/r_{ji}) \in \mathbb{R}^4$ ,  $j \in \{1, \dots, N+M\} \setminus \{i\}$ , are extended relative coordinates. Then we decompose  $\tilde{S}(\mathbf{r}; \mathbf{R})$  into the sum of contributions from each particle and an extra asymptotic term, i.e.,

$$\tilde{S}(\mathbf{r}; \mathbf{R}) = \tilde{S}_{\text{asy}}(\tilde{\mathbf{r}}) + \sum_{i=1}^{N+M} \tilde{S}_i(\mathcal{R}^i). \quad (5)$$

We define  $\tilde{S}_i$  in a way that guarantees the symmetric property. We first construct a series of embedding networks  $\text{Net}_{\text{ebd}}^{\alpha_i \alpha_j}$ , each mapping the extended relative coordinates  $\mathbf{s}(\mathbf{r}_{ji})$  to  $M_2$  components. Here  $\alpha_i$  denotes the type of particle  $i$ , and the parameters of  $\text{Net}_{\text{ebd}}^{\alpha_i \alpha_j}$  depend on the types of both particle  $i$  and its neighbor particle

$j$ . The embedding matrix  $\mathcal{G}^i \in \mathbb{R}^{(N+M-1) \times M_2}$  and the encoded feature matrix  $\mathcal{D}^i \in \mathbb{R}^{M_2 \times 4}$  of particle  $i$  are then defined as

$$(\mathcal{G}^i)_{jk} = (\text{Net}_{\text{ebd}}^{\alpha_i \alpha_j}(\mathbf{s}(\mathbf{r}_{ji})))_k, \quad (6)$$

$$\mathcal{D}^i = (\mathcal{G}^i)^T \mathcal{R}^i. \quad (7)$$

By definition one can check that the feature matrix  $\mathcal{D}^i$  is invariant under the permutation of particles in the same type, and its  $M_2 \times 4$  components are finally reshaped into a vector to serve as the input of a fitting network  $\text{Net}_{\text{fit}}^{\alpha_i}$  and yield  $\tilde{S}_i$ .

The remaining term  $\tilde{S}_{\text{asy}}(\tilde{\mathbf{r}})$  should also be symmetric and serve the additional purposes of making the trial wave-function close to some desired asymptotic properties. This term has the form

$$\begin{aligned} \tilde{S}_{\text{asy}}(\tilde{\mathbf{r}}) = & - \sum_{k=N+1}^{N+M} Z_{k-N} \sum_{i=1}^N \frac{r_{ik} + f_{\text{dec}} r_{ik}^2}{r_{ik} + 0.5} \\ & + \sum_{i=1}^N \sum_{j=i+1}^N \frac{r_{ij}}{r_{ij} + 1}, \end{aligned} \quad (8)$$

where  $f_{\text{dec}}$  is a positive scalar as decay factor. The first purpose is to ensure that  $\Psi(\mathbf{r}; \mathbf{R})$  is square integrable when  $f_{\text{dec}}$  is large enough such that  $\Psi(\mathbf{r}; \mathbf{R})$  has exponential decay for the electrons that are far away. The second purpose is related to the so-called *cusps* conditions, meaning that the trial wave-function has the correct singular behavior when two particles are close to each other [57]. If we let  $\log(\Psi^2(\mathbf{r}; \mathbf{R})) = \tilde{S}_{\text{asy}}(\tilde{\mathbf{r}})$ , it can be shown from (8) that for  $1 \leq i < j \leq N$ ,  $N+1 \leq k \leq N+M$ ,

$$\left. \frac{1}{\Psi} \frac{\partial \Psi}{\partial r_{ik}} \right|_{r_{ik}=0} = -Z_{k-N}, \quad \left. \frac{1}{\Psi} \frac{\partial \Psi}{\partial r_{ij}} \right|_{r_{ij}=0} = \frac{1}{2}. \quad (9)$$

This indicates  $\Psi(\mathbf{r}; \mathbf{R})$  meets the cusp conditions of both the electron-nuclear pairs and unlike spin pairs (see e.g., [20, 57] for more details). In numerical computation we find that adding  $\tilde{S}_{\text{asy}}(\tilde{\mathbf{r}})$  makes the training process much more stable, even though the cusp conditions are not strictly satisfied due to the influence of  $\tilde{S}_i$  and  $A(\mathbf{r})$  on the terms in (9).

We denote all the parameters in the DNNs ( $\text{Net}_{\text{anti}}^\uparrow$ ,  $\text{Net}_{\text{anti}}^\downarrow$ ,  $\text{Net}_{\text{odd}}^\uparrow$ ,  $\text{Net}_{\text{odd}}^\downarrow$ ,  $\text{Net}_{\text{ebd}}^{\alpha_i \alpha_j}$ , and  $\text{Net}_{\text{fit}}^{\alpha_i}$ ), the two scalar factors ( $f_{\text{odd}}$  and  $f_{\text{dec}}$ ) together as  $\boldsymbol{\theta}$  and the associated trial wave-function as  $\Psi_{\boldsymbol{\theta}}(\mathbf{r})$  (below for convenience we ignore the dependence on the clamped ion positions).  $\boldsymbol{\theta}$  is initialized randomly from a Gaussian distribution without any pre-training on pre-calculated wave-functions. We use VMC to optimize the trial wave-function. Specifically, we keep track of  $N_{\text{wk}}$  walkers to approximate the squared wave-function through an empirical distribution. The learning process consists of two phases, the sampling phase and optimization phase, which we proceed with alternatively. In the sampling

phase of step  $t$ , we run several steps of the Metropolis-Hasting algorithm to update the positions of the walkers, according to a target probability proportional to  $\Psi_{\theta_t}^2(\mathbf{r})$ . In the optimization phase of step  $t$ , we aim to minimize the second moment of the local energy  $E_{\text{loc}}(\mathbf{r})$  with respect to a fixed reference energy  $E_{\text{ref}}$ . Here the local energy is defined as  $E_{\text{loc}}(\mathbf{r}) := \hat{H}\Psi_{\theta}(\mathbf{r})/\Psi_{\theta}(\mathbf{r})$ . Accordingly, the objective function has the explicit form

$$\Omega_{E_{\text{ref}}}(\theta) := \frac{\int \Psi_{\theta}^2(\mathbf{r})(E_{\text{loc}}(\mathbf{r}) - E_{\text{ref}})^2 d\mathbf{r}}{\int \Psi_{\theta}^2(\mathbf{r}) d\mathbf{r}}.$$

In numerical computation, in order to reduce the variance when evaluating the objective function, we use a technique called correlated sampling. Assuming the walkers' current positions  $(\mathbf{r}^{(1)}, \mathbf{r}^{(2)}, \dots, \mathbf{r}^{(N_{\text{wk}})})$  approximate the distribution  $\Psi_{\theta_t}^2(\mathbf{r})$  well, we define a reweighting factor  $w_i := \Psi_{\theta}(\mathbf{r}^{(i)})/\Psi_{\theta_t}(\mathbf{r}^{(i)})$  and rewrite the objective function as

$$\begin{aligned} \Omega_{E_{\text{ref}}}(\theta) &= \frac{\int \Psi_{\theta_t}^2(\mathbf{r})(\Psi_{\theta}^2(\mathbf{r})/\Psi_{\theta_t}^2(\mathbf{r}))(E_{\text{loc}}(\mathbf{r}) - E_{\text{ref}})^2 d\mathbf{r}}{\int \Psi_{\theta_t}^2(\mathbf{r})(\Psi_{\theta}^2(\mathbf{r})/\Psi_{\theta_t}^2(\mathbf{r})) d\mathbf{r}} \\ &\approx \frac{\sum_{i=1}^{N_{\text{wk}}} w_i^2 (E_{\text{loc}}(\mathbf{r}^{(i)}) - E_{\text{ref}})^2}{\sum_{i=1}^{N_{\text{wk}}} w_i^2}. \end{aligned}$$

Note here we take  $\theta_t$  as constants and view both  $w_i$  and  $E_{\text{loc}}(\mathbf{r}^{(i)})$  as functions of the parameters  $\theta$  given the walker's position  $\mathbf{r}^{(i)}$ . The gradient  $\nabla_{\theta}\Omega_{E_{\text{ref}}}(\theta)$  is computed by the backpropagation algorithm and used to update the parameters through  $\theta_{t+1} = \theta_t - \eta \nabla_{\theta}\Omega_{E_{\text{ref}}}(\theta_t)$ , with  $\eta$  being the learning rate. Motivated by the idea of stochastic gradient descent (SGD), we actually evaluate  $\nabla_{\theta}\Omega_{E_{\text{ref}}}(\theta)$  with a random batch of data  $i \in \mathcal{B} \subseteq \{1, \dots, N_{\text{wk}}\}$  and update  $\theta_t$  with a few steps.

TABLE I: Ground-state energy of several systems obtained by DeepWF. The bond length of  $\text{H}_2$ ,  $\text{LiH}$ , and  $\text{H}_{10}$  is 1.4, 1.62, and 1.8  $a.u.$ , respectively. The benchmarks for  $\text{H}_2$ ,  $\text{Be}$ ,  $\text{LiH}$ , and  $\text{B}$  are taken from the Computational Chemistry Comparison and Benchmark (CCCBDB) DataBase [58], at the level of configuration interaction, singles and doubles (CISD) theory. The benchmark for  $\text{H}_{10}$  is taken from [31], at the level of multi-reference configuration with the Davidson correction (MRCI+Q) [7]. All the benchmark results are extrapolated to the complete basis set (CBS) limit. The relative difference (Rel. Diff) is reported.

System	DeepWF [ $a.u.$ ]	Benchmark [ $a.u.$ ]	Rel. Diff
$\text{H}_2$	-1.1738	-1.1741	0.26%
$\text{He}$	-2.9039	-2.9029	-0.03%
$\text{LiH}$	-7.8732	-8.0243	1.88%
$\text{Be}$	-14.6141	-14.6190	0.03%
$\text{B}$	-24.2124	-24.6006	1.58%
$\text{H}_{10}$	-5.5685	-5.6655	1.71%

We apply DeepWF to a series of benchmark tests. In all the tests, we first optimize the parameters  $\theta$  using the algorithms described above. We then fix the optimized

FIG. 2: Potential energy per atom  $E(L_b, N)/N$  vs. bond length  $L_b$  for (a)  $\text{H}_2$  ( $N = 2$ ), and (b)  $\text{H}_{10}$  ( $N = 10$ ). The benchmark result for  $\text{H}_2$  is obtained using the PySCF package [59], at the level of full CI. The benchmark result for  $\text{H}_{10}$  is taken from [31], at the level of MRCI+Q [7]. Both the benchmark results are extrapolated to the CBS limit.

FIG. 3: Spatial distribution functions of electrons in different systems. (a) radial distribution of 2 electrons of He's, 4 electrons of Be's, and 5 electrons of B's; (b) axial distribution of 2 electrons of  $\text{H}_2$ 's and 4 electrons of  $\text{LiH}$ 's.

parameters  $\theta^*$  and run Monte Carlo simulation to obtain the electronic distribution proportional to  $\Psi_{\theta^*}^2(\mathbf{r}; \mathbf{R})$  and evaluate  $E[\Psi_{\theta^*}]$  as the ground state energy. In Table I, we present the ground state energies of  $\text{H}_2$ ,  $\text{He}$ ,  $\text{LiH}$ ,  $\text{Be}$ ,  $\text{B}$ , and a chain of 10 hydrogen atoms under open boundary conditions. Note that for  $\text{H}_2$  and  $\text{He}$  we don't have the anti-symmetric part in the wave-function. Overall the ground-state energies obtained by DeepWF show great consistency with the benchmarks. However, as the number of electrons increases, the accuracy deteriorates.

In Fig. 2, we plot the potential energy curves of  $\text{H}_2$  and  $\text{H}_{10}$  as a function of bond length. The result for  $\text{H}_2$  is very close to the benchmark. For  $\text{H}_{10}$ , the DeepWF shows a good relative energy, with the correct prediction of local minimum, but is still a bit above the benchmark result.

Finally, Fig. 3 plots the spatial distributions of electrons in different systems. In the case of radial distribution functions (Fig. 3 (a)) of single atoms  $\text{Be}$  and  $\text{B}$ , it is remarkable that the DNN-based wave-function learns from scratch the shell structure of the electrons, with-

out any prior knowledge like atomic orbitals. In addition, Fig. 3 (b) shows the axial distribution functions of the electrons in diatomic molecules  $H_2$  and  $LiH$ . We note that the shape of the axial distribution function of  $H_2$  is not symmetric with respect to the locations of the two hydrogen atoms. This is due to the fact that we did not impose discrete symmetry in the trial wave-functions, therefore such symmetry is not exactly achieved in the final solution.

What is appealing to us is the simplicity of the proposed approach. Obviously there is a huge room for further improvement. In terms of the representation of DeepWF, the symmetric part is relatively general, considering the success of a similar version in representing the inter-atomic potential energy surface. However, the anti-symmetric ansatz, although appealing due to its quadratic scaling, might not be sufficient in representing the electronic correlations caused by the Pauli exclusion rule. Second, in terms of optimization, techniques for accelerating VMC through more efficient sampling (see e.g. [60, 61]) can be directly adapted into our DeepWF method. Optimization method other than the SGD-like correlated sampling method can also be employed. In any case, we hope that ideas presented here will add some ammunition to the heroic endeavor of attempting to solve the many-body Schrödinger equation.

The authors acknowledge M. Motta for helpful discussions. This work is supported in part by Major Program of NNSFC under grant 91130005, ONR grant N00014-13-1-0338 and NSFC grant U1430237. We are grateful for the computing time provided by the High-performance Computing Platform of Peking University and the TIGRESS High Performance Computing Center at Princeton University.
